Sepsis is a considerable health problem and a burden on the health care system. Endotoxin, or lipopolysaccharide (LPS), present in the outer membrane of gram-negative bacteria, is responsible for more than 50% of the sepsis cases and is, therefore, a legitimate target for therapeutic approaches against sepsis. In this study, we selected and characterized a llama single-chain antibody fragment (VHH) directed to Neisseria meningitidis LPS. The VHH, designated VHH 5G, showed affinity to purified LPS as well as to LPS on the surfaces of the bacteria. Epitope mapping using a panel of N. meningitidis mutants revealed that VHH 5G recognizes an epitope in the inner core of LPS, and as expected, the VHH proved to have broad specificity for LPS from different bacteria. Furthermore, this VHH blocked binding of LPS to target cells of the immune system, resulting in the inhibition of LPS signaling in whole blood. Moreover, it was found to remove LPS efficiently from aqueous solutions, including serum. The selected anti-LPS VHH is a leading candidate for therapies against LPS-mediated sepsis.

Lipopolysaccharide (LPS) (or endotoxin), present exclusively in the outer leaflet of the outer membrane of gram-negative bacteria, is one of the major contributors to innate immunity (6). This nonspecific immune response is capable of destroying invading pathogens, but if overstimulated, it can also initiate toxic effects against the host. LPS contributes to toxicity when it is released into the blood circulation after a bacterial infection. This undesirable interaction between the host and the pathogen leads to the fatal syndrome known as sepsis (21). To exert its pathological effect at low concentrations, LPS interacts with high-affinity receptors present both on the surfaces of host cells and in plasma. Interaction of the LPS with these receptors results in an inflammatory response, occasionally with deleterious effects for the host.

The gram-negative bacterium Neisseria meningitidis is an important cause of meningitis and sepsis in children and young adults. Despite advances in supportive care, invasive meningococcal disease still forms a major health threat. There is an urgent requirement for the development of novel therapies against such disease, since an effective vaccine against serogroup B of N. meningitidis, which is responsible for most cases of meningitis and septicaemia in industrialized countries, is currently not available. Moreover, development of an effective polysaccharide-based vaccine against serogroup B strains, in the same way as is done for the other serogroups of N. meningitidis (23), may prove unsuccessful, since the polysaccharides of the serogroup B capsule are also found on human neuronal-cell adhesion molecules and other surface-expressed molecules. These polysaccharides can be classified as autoantigens and may therefore cause a potential problem of autoimmunity when used as a vaccine (13, 14). Therefore, alternative approaches to fighting neisserial infections are sought. LPS is a major contributor to the health threat imposed by N. meningitidis, and therefore, therapeutic measures in the fight against the disease, and sepsis in general, are focused on this molecule.

Structures of diverse LPS molecules revealed that the lipid A moiety and the inner core region of these molecules are considerably conserved among the gram-negative bacteria. Antibodies raised against these conserved regions are predicted to provide protection against a broad range of gram-negative bacteria (4, 10). Twelve distinct immunotypes of meningococcal LPS (L1 to L12) can be defined by monoclonal antibody reactivity (24). This heterogeneity is caused by controlled gene expression of the genes involved in LPS biosynthesis and by phase variation of some of these genes (18). Genes involved in the biosynthesis of the inner core are less subjected to phase variation, which makes this structure relatively well conserved, except for some variations in the presence and the position of a phosphoethanolamine on one of the heptoses (HepII) in the backbone of the inner core (22).

Camelidae (camels and llamas) possess, in addition to the conventional immunoglobulins formed by the association between a heavy and a light chain, single-chain antibodies formed by a heavy chain only (15). These single-chain antibodies in general, and their antigen-binding domains (called VHHs) in particular, are interesting polypeptides with broad biotechnological applications (11, 12, 36). Using phage display, several VHHs that recognize antigens with diverse structure and characteristics have been selected in vitro (25). Furthermore, by proper design of the selection procedure, VHHs with specific properties, such as functioning in high detergent concentra-

Published ahead of print on 23 August 2006.
tions (11), inhibiting enzyme activities (20), or preventing bacteria-pherage infection (9), could be selected.

The aim of this study was to explore the possibilities of using anti-LPS VHHs as a therapy against sepsis. Such VHHs should have several properties: they should be insensitive to the variations present in the LPS molecules and should, therefore, recognize an epitope in the conserved inner core of the LPS molecule. Monoclonal antibodies directed against this region of the LPS molecule proved to be broadly cross-reactive, recognizing LPS from different phylogenetic strains (4, 7, 8, 10). Furthermore, the inner core of the LPS molecules was shown to be accessible in fully encapsulated intact N. meningitidis cells, even to the larger conventional antibodies (22). Additionally, successful anti-LPS VHHs should be able to compete with the high-affinity LPS-binding proteins present on different cells of the immune system and in plasma. In this paper, we describe the selection of such a VHH that shows high specificity to LPS molecules from different N. meningitidis serogroup B strains and additionally displays cross-reactivity to LPS from other gram-negative bacteria. Furthermore, we demonstrate the ability of this VHH to detoxify LPS in whole blood and to efficiently deplete LPS from solutions when immobilized to a solid support.

MATERIALS AND METHODS

Selection of anti-LPS VHHs. A nonimmune VHH phage display library displaying a diversity of more than $10^9$ different VHHs was generated from the peripheral blood lymphocytes of eight different young llamas and kindly provided by Unilever Research (Vlaardingen, The Netherlands). Phage display (17) was used to select phages that specifically bind to LPS as follows. Nunc Polysorb immunoplates were coated overnight at 4°C with various concentrations of LPS immunotype L3 from N. meningitidis strain H44/76 in phosphate-buffered saline (PBS). The wells were blocked with 2% bovine serum albumin (BSA) in PBS. Subsequently, phages were preincubated in 1% BSA, added to the wells, and incubated for 2 h at room temperature. After extensive washing with PBS containing 0.05% Tween 20 (PBST) and PBS, bound phages were eluted with 100 mM triethylamine by 15 min of incubation at room temperature. The eluted phages were directly neutralized by the addition of 1 M Tris-HCl, pH 7.5. Phages were rescued by infection of the Escherichia coli strain TG1 [supE lacDΔ (θ lacIqag proAB) lacUV5 (θ lacIqag proAB lacZΔM15)] and selected on agar plates containing ampicillin. For the production of phages, E. coli containing phage-mids was superinfected with helper phage VCSM13 (Stratagene), and phage particles were grown overnight at 37°C. The selected phages were panned a second time on wells coated with LPS as described above, and phages from single colonies were tested for their binding specificities for LPS using an uncoated, empty plate as a negative control.

Purification of anti-LPS VHHs. VHHs were produced in E. coli in the presence of 1 mM isopropyl-β-D-thiogalactopyranoside for 4 to 5 h at 37°C. Subsequently, VHHs were purified from the periplasmic fraction after spheroplasting of the cells (39). The periplasmic fractions were applied on BD Talon metal-affinity resin (BD Biosciences), and bound His-tagged VHHs were washed and eluted according to the manufacturer’s protocol. The eluted anti-LPS VHHs were extensively dialyzed against PBS and stored at −20°C.

To obtain highly purified VHHs that do not show any priming activity in whole blood, His-tagged VHHs were produced in the yeast Saccharomyces cerevisiae and purified from the extracellular medium using metal affinity chromatography. VHHs, which were eluted with 500 mM imidazole in PBS, were dialyzed against 25 mM sodium acetate buffer, pH 5.0, and loaded on Unospher Q (Bio-Rad). VHHs were found in the flowthrough, whereas many contaminating proteins remained bound to the column. The VHHs were concentrated by binding to Unospher S (Bio-Rad) after the pH was calibrated to 3.8 using acetic acid. Bound VHHs were eluted with 500 mM NaCl in the same buffer. Finally the VHHs were concentrated by binding to Unisphere S (Bio-Rad) after the pH was calibrated to 3.8 using acetic acid.

VHHs, which were eluted with 500 mM imidazole in PBS, were dialyzed against 0.05% human serum albumin (RPMI/HSA). Subsequently, 100 μl of LPS (2 μg/ml) was added and incubated for 1 h at room temperature. Talon beads were collected by centrifugation, and the supernatant fractions, which contained the unbound LPS, were assayed for priming of human whole blood (31).

Various VHHs were used as negative controls in the different assays depending on how these VHHs were produced and purified and whether they were suitable for the desired experiment. These VHHs were selected against different antigens, and sequence analysis confirmed the presence of the VHH. Furthermore, these VHHs were functional in binding of their corresponding antigens.

Whole-cell enzyme-linked immunosorbent assay (ELISA). Wells of Nunc Maxisorp plates were coated overnight at 37°C with 100 μl of heat-inactivated bacteria (optical density at 600 nm of 0.1). The wild-type N. meningitidis strain H44/76 (immunotype L3) (16) and its galE (19), rfaC (28), icaA (33), and lpaC (26) mutants were utilized to determine the epitope recognized by the isolated VHHs. Plates were blocked with 2% BSA in PBS, washed with PBS, and incubated with different dilutions of the VHHs (1 mg/ml) for 1 to 2 h at room temperature. Plates were washed with PBST and PBS prior to incubation with rabbit anti-llama heavy-chain serum for 1 h at room temperature. Subsequently, plates were washed with PBST and PBS and incubated with peroxidase-conjugated goat anti-rabbit immunoglobulin Gs for 1 h at room temperature. Peroxidase activity was developed with o-phenylenediamine in the presence of H₂O₂. Absorptions at 490 nm were measured using a microtiter plate reader.

LPS priming of human whole blood. LPS priming was measured using the oxidative-burst assay (31). Plates were filled with different dilutions of LPS dissolved in 5 mM glucose (PBS-G) were incubated with VHHs or buffer (both 10 μl) for about 10 min at room temperature. Subsequently, EDTA-anticoagulated blood obtained from healthy volunteers was diluted 10-fold with PBS-G, and 90 μl was added to the LPS samples. The mixtures were incubated for 30 min at 37°C under constant agitation. Enhanced-chemiluminescence responses were measured using a Centro LB960 luminometer (Berthold Technology, Bald Wildbad, Germany) in 10 μl of the reaction mixtures after a 10-fold dilution with PBS-G. LPS was a generous gift from L. Galgani (University of Rome, Italy).

LPS immunoprecipitation. About 4 μg of the anti-LPS VHHs 7F, 5G, 7H, and 12H and of an irrelevant VHH (C) were bound to 25 μl of Talon beads (50% slurry) for 20 min at room temperature in 250 μl PBS. The beads were washed with PBS, and subsequently, 500 μl of the different LPS solutions (2 μg/ml) were added and incubated for 1 h at room temperature. The beads were washed three times with PBS, and ~1/3 of the bound LPS was analyzed using sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) (15% resolving gels) and silver staining (32). The amounts of LPS bound to the beads were deduced by comparison with 1/3 of the total amount of LPS used in the experiment (standard [std]). L3, L8, and goE LPS were isolated from the wild-type N. meningitidis strain H44/76 of L3 (16) and L8 (24) immunotypes and from the galE mutant strain (19), respectively. Bordetella pertussis LPS was a generous gift from J. Geurtsen. B4:O111 LPS from E. coli and Re LPS from Salmonella enterica serovar Typhimurium were purchased from Sigma-Aldrich.

LPS depletion. The VHHs were coupled to Talon beads as described above. Subsequently, 100 μl of L3 LPS (2 μg/ml) was added and incubated for 1 h at room temperature. Talon beads were collected by centrifugation, and the supernatant fractions, which contained the unbound LPS, were assayed for priming of human whole blood (31).

Various VHHs were used as negative controls in the different assays depending on how these VHHs were produced and purified and whether they were suitable for the desired experiment. These VHHs were selected against different antigens, and sequence analysis confirmed the presence of the VHH. Furthermore, these VHHs were functional in binding of their corresponding antigens.

Binding of FITC-labeled LPS to human monocytes. LPS was isolated from N. meningitidis strain H44/76 by the hot-phenol extraction method (38). Labeling with fluorescein isothiocyanate (FITC-LPS) was performed as described previously (30). Peripheral blood mononuclear cells (PBMC) and neutrophils were isolated from heparin-anticoagulated blood obtained from healthy volunteers using Histopaque-Ficoll-Paque gradient centrifugation (30). The binding experiments and analysis of the fluorescence-activated cell sorting data were done essentially as described previously (37). Briefly, FITC-L3 LPS from N. meningitidis or FITC-Re595 LPS from Salmonella enterica serovar Minnesota was incubated in the presence of 0.2, or 10 μg LPS with a PBMC-neutrophil mixture (200 cells/ml) and 2% human pooled serum in a final volume of 70 μl for 30 min with gentle shaking at 37°C in RPMI 1640 (Cambrex) supplemented with 0.05% human serum albumin (RPMI/HSAS). Subsequently, 1 ml of RPMI/HSAS was used as an inhibitor in the assay (34).

LPS depletion with VHHs coupled to Talon beads was also studied using the oxidative-burst assay. VHHs coupled to Talon beads by means of their His tag were used to capture LPS from a 100-μl solution (2 μg/ml) during 2 h at room temperature. The amount of LPS in the unbound fraction was measured in the oxidative-burst assay. The chemiluminescence responses were compared with those induced with equivalent volumes of untreated LPS solutions. Since VHHs were stripped from Talon in the presence of plasma, VHH 5G was coupled to N-hydroxysuccinimide-activated Sepharse (Amersham Biosciences) according to the manufacturer’s protocol to investigate sequestration of LPS by the VHHs from serum.

RESULTS

Selection of llama VHHs against LPS. To obtain llama VHHs directed to *N. meningitidis* LPS, phage display selection was performed on purified L3 LPS, coated directly into Nunc Polysorb wells, using a VHH phage display library generated from nonimmunized llamas. After two rounds of selection, a 20- to 30-fold enrichment compared with empty wells was reached. Monoclonal phages were subsequently tested for binding to the LPS compared with binding to empty wells using ELISA. Sequencing of several of the clones that showed a positive signal in ELISA yielded four different VHHs with unique sequences. Whereas the lengths of CDR3 complementarity-determining regions varied between the different VHHs, they all contained a high number of positively charged and aromatic amino acids (not shown). Strikingly, both these amino acid forms are frequently found between the different VHHs, they all contained a high number of CDR3 complementarity-determining regions varied between the different VHHs with unique sequences. Whereas the lengths of CDR3 complementarity-determining regions varied between the different VHHs, they all contained a high number of positively charged and aromatic amino acids (not shown).

To study the function of these VHHs in more detail, their expression in *E. coli* was induced with isopropyl-β-D-thiogalactopyranoside and the proteins produced were isolated from the periplasmic fraction and purified by affinity chromatography on Talon beads. Except for that of VHH 12H, the yields of the VHHs were satisfactory (Fig. 1A). Interestingly, the VHH 5G and 12H samples contained large amounts of contaminating LPS (Fig. 1A, lanes 3 and 5). Treatment of these samples with phenol resulted in the fractionation of the LPS in a pure form into the water phase. Analysis of these phenol extracts by mass spectrometry confirmed the presence of monophosphoryl-

To confirm the specific association of the *E. coli* LPS with the selected VHHs, the VHHs were denatured by incubation with 8 M urea at room temperature while they were coupled to Talon beads. After removal of the urea and resuspension of the beads in PBS, the VHHs were analyzed with SDS-PAGE (Fig. 1B, odd-number lanes). Most of the contaminating *E. coli* LPS was lost from the VHH 5G sample after treatment with urea (Fig. 1B, compare lanes 5 and 7). Similar results were obtained with VHH 12H (result not shown). This observation indicates that *E. coli* LPS was specifically bound by the VHHs and that this binding was lost after denaturation of the VHH with urea. To investigate whether denatured VHHs renatured correctly after removal of urea, *N. meningitidis* L3 LPS was added to the VHHs and the amounts of LPS bound were analyzed (Fig. 1B, even-number lanes). The amounts of LPS precipitated by the renatured VHHs were similar to those immunoprecipitated by equivalent amounts of native VHHs (Fig. 1B, compare lanes 2 and 4, lanes 6 and 8, and lanes 10 and 12 for VHH 7F, VHH 5G, and VHH 7H, respectively), indicating that the VHHs regained their full activity after denaturation and renaturation. It should be noted that even in the presence of contaminating *E. coli* LPS, VHH 5G bound additional L3 LPS (Fig. 1B, compare lanes 5 and 6), suggesting that VHH 5G has a high capacity to bind LPS. An aspecific VHH (C) did not bind any LPS in its native form (Fig. 1B, lanes 13 and 14), nor after denaturation and renaturation (not shown).

Specificities of the VHHs. VHHs produced in *E. coli* contained contaminating LPS with the same size as *N. meningitidis* L3 LPS, which thwarted the interpretation of the results of the immunoprecipitations to some extent. Furthermore, contaminating LPS may compromise the function of the VHHs in
shorter L8 and noprecipitated (Fig. 2A). Since the VHHs also recognized the indicating that all the LPS used in the experiment was immuno

tics was specific, since an irrelevant VHH did show no or barely any binding of the other LPS species tested.

**Epicope mapping.** To determine the binding sites of the different VHHs in the LPS in more detail, various strains of *N. meningitidis* which express LPS molecules with defined truncations in the oligosaccharide moiety (see Fig. 3F) were used in a whole-cell ELISA. As a control, the *lpxA* mutant strain, which totally lacks LPS, was used (26). All four VHHs recognized the wild-type *N. meningitidis* strain H44/76 expressing L3 LPS, as well as the mutant strains expressing shorter LPS molecules (Fig. 3). Since VHH 5G bound the *rfaC* mutant strain, which expresses an LPS molecule consisting of lipid A and 2-keto-3-deoxyoctulosonic acid (KDO) only, but failed to bind the LPS-deficient *lpxA* mutant strain, the data indicate that VHH 5G is an LPS-specific antibody and that its epitope must reside in the lipid A and KDO regions. The lack of binding of VHH 5G with the *lpxA* mutant was not due to shielding by capsule, since VHH 5G also did not react with the *lpxA* *cps* double mutant (3), which lacks both LPS and capsule (results not shown). Interestingly, this VHH reacted better with *N. meningitidis* strains expressing shorter LPS molecules than with the wild-type strain, suggesting that the full-length LPS shields the epitope to some extent. Remarkably, the VHHs 7F, 7H, and 12H reacted with the LPS deletion strain, suggesting that they interact with other antigens in addition to LPS or that they interact indirectly with LPS through unidentified components. The binding of the different VHHs to the *N. meningitidis* strains was specific, since an irrelevant VHH did not show any interaction with the different *N. meningitidis* strains studied (Fig. 3E).

The three VHHs that reacted with the *lpxA* mutant strain in a whole-cell ELISA can perfectly sequester LPS and detoxify it (see below). However, since it is not clear whether these VHHs bind directly to LPS or bind LPS through an unidentified component, additional studies are required to fully characterize these VHHs before using them for any application. For these reasons, only VHH 5G was used in the following studies.

**Inhibition of LPS binding to human monocytes.** LPS interacts with high-affinity receptors present on immune cells and in plasma. To investigate whether anti-LPS VHH can compete with these high-affinity receptors, the binding of FITC-labeled L3 LPS from *N. meningitidis* and Re595 LPS from *Salmonella* serovar Minnesota to PBMCs was studied in the absence or presence of VHH 5G. The FITC fluorescence that was associated with the monocytes was displaced in the presence of VHH 5G (Fig. 4). Both FITC-labeled L3 LPS from *N. meningitidis* and Re595 LPS from *Salmonella* serovar Minnesota were displaced by VHH 5G but not by the irrelevant VHH (Fig. 4, compare A with B and C with D, respectively). Inhibition of LPS binding to CD14-expressing cells was dose dependent. This was clearly shown in the case of *Salmonella* serovar Minnesota LPS (Fig. 4C). Inhibition of the LPS binding did not result from shielding of the LPS receptor CD14 by a broader range of LPS molecules. Consistently, VHHs 5G, 7H, and 12H also precipitated LPS from *E. coli* B4:O111, Re LPS from *Salmonella* serovar Typhimurium, and LPS from *B. pertussis* (Fig. 2B). VHH 7F, on the other hand, barely showed binding to LPS molecules other than those of *N. meningitidis* (Fig. 2B, lanes 3, 9, and 15), suggesting that this VHH is more specific to *N. meningitidis* LPS. Although the irrelevant VHH (C) showed considerable binding of *N. meningitidis* L8 LPS (Fig. 2A, lane 13), it showed no or barely any binding of the other LPS species tested.

*FIG. 2.* Immunoprecipitation of free LPS. SDS-PAGE gel showing the amounts of LPS that were immunoprecipitated by VHHs immobilized to Talon beads. (A) Three LPS derivatives from *N. meningitidis* H44/76 (L3, L8, and galE) were efficiently precipitated by all four anti-LPS VHHs. (B) LPS from *E. coli* B4:O111, Re LPS from *Salmo-

nella* serovar Typhimurium, and LPS from *B. pertussis* were precipitated with the VHHs 5G, 7H, and 12H but not with VHH 7F. In both panels, the lanes marked std represent input LPS, i.e., the maximal amount of LPS that could be immunoprecipitated. The lanes marked C show LPS that was precipitated with an irrelevant VHH. Lane 1 contains the molecular mass standard in kDa (indicated at the left). In panel B, the larger part of the gel is shown to include the O antigen containing high-molecular-mass LPS bands of *E. coli* B4:O111.
the VHH, since the labeled CD14-specific MAb LeuM3-PE could still bind to the cell, whereas monocytes incubated with the anti-CD14 MAb 60bca did not bind any LeuM3-PE afterwards (result not shown). CD14-specific MAb LeuM3-PE was used to gate the cells that bind LPS (Fig. 4E). These results indicate that the anti-LPS VHH is able to block binding of LPS to its high-affinity receptor present on PBMCs.

**Detoxification of LPS.** During sepsis, LPS stimulates the immune cells to massively produce inflammatory responses. The anti-LPS VHH was found to reduce binding of LPS to target cells efficiently. To study whether this inhibition prevents the response of these cells to LPS, priming of whole blood with *N. meningitidis* L3 LPS (34) to produce an oxidative burst in response to fMLP was studied in the presence or absence of VHH 5G. In contrast to an irrelevant VHH, VHH 5G inhibited LPS signaling very efficiently (Fig. 5). The inhibition exerted by the anti-LPS VHH was almost equal to that found in the presence of the anti-CD14 MAb 60bca, known for its blocking activity (34). However, MAb 60bca blocks the binding site of LPS on effector cells, whereas VHH binds to
LPS and shows no interaction with the effector cells. This may explain the higher molar concentration needed for VHH than for MAb 60bca (Fig. 5).

Sequestration of LPS. Different LPS forms were efficiently immunoprecipitated by the VHHs. To investigate whether this depletion is sufficient to detoxify a solution that was spiked with LPS, immobilized VHHs were used to bind LPS and the unbound fractions were used to prime whole blood. The oxidative burst produced by the solutions treated with the VHHs was compared with that produced by the untreated solution. To demonstrate the specificity of the VHHs, empty Talon beads and an irrelevant VHH were used. Furthermore, the inhibition of LPS signal by the anti-CD14 MAb 60bca was also measured. All VHHs depleted LPS very efficiently (Fig. 6).

When the same volumes of preincubated solution as of the untreated solution were used in the assay, the mean luminescence was reduced by more than 90% (Fig. 6). Even when 10-fold more preincubated solution was used in the assay, the reduction in mean luminescence was higher than 70%. These results indicate that immobilized anti-LPS VHHs sequestered most of the LPS spiked into the PBS solution. The depletion of the LPS was not due to aspecific binding of LPS to Talon beads, since empty beads did not show any reduction of the amount of LPS in the solution (Fig. 6). The irrelevant VHH,

FIG. 6. Sequestration of the L3 LPS from an aqueous solution by VHHs. Graph showing the amounts of luminescence (y axis) produced by an LPS solution (2 μg/ml) before (input) and after incubation with the indicated anti-LPS VHHs, which were immobilized through the histidine tag to Talon beads. As controls, empty Talon beads (BD) and beads loaded with an irrelevant VHH (C) were used. Both equivalent amounts (−1) and 10-fold the amount (−10) of input were used in the assay. The inhibition of luminescence by the anti-CD14 MAb 60bca is also indicated. The experiment was repeated three times, and error bars are indicated.
on the other hand, depleted about 49% of the LPS (Fig. 6). Apparently, due to its hydrophobic nature, LPS shows aspecific interaction with different proteins. The specificity of the anti-LPS VHVs was clear when a 10-fold-larger volume was tested. Whereas anti-LPS VHVs still reduced the mean luminescence up to 70 to 80%, the irrelevant VH1 did not prevent a strong response. This result indicates that LPS depletion by the anti-LPS VHVs is specific and that such depletion can be used to detoxify aqueous solutions.

The His-tagged VHVs dissociated from Talon beads in plasma and serum due to the anticoagulant (EDTA) used for the preparation of these fractions (not shown). In order to test the ability of the VHVs to sequester LPS from a complex solution, such as serum or plasma, VH5 5G was chemically coupled to Sepharose beads. VH5 5G coupled in this way was found to efficiently deplete LPS spiked into serum (not shown). Together, these results indicate that anti-LPS VHVs can be used to deplete LPS from different solutions, including plasma, a property that can be utilized in therapy in the fight against sepsis.

**DISCUSSION**

A llama single-chain antibody fragment recognizing LPS was selected from a VH phage library derived from mRNA of peripheral blood lymphocytes of nonimmunized llamas. This VH has the ability to capture LPS molecules from an aqueous solution very efficiently. It recognized LPS molecules present in bacteria, as well as free LPS molecules purified from different sources. The isolated VH1 was also able to disturb binding of LPS to their targets and to disrupt LPS signaling that results in the generation of the effector molecules and the pathological condition of sepsis.

The presence of antibodies recognizing LPS in nonimmunized young llamas is not surprising, since even at a young age, llamas may encounter gram-negative bacterial infections. Immunization of llamas with purified LPS from *N. meningitidis* did not result in a detectable immune reaction, and attempts to select an anti-LPS VH1 from a phage phage library derived from mRNA of peripheral blood lymphocytes of an immunized llama failed (results not shown). Possibly purified LPS molecules are not immunogenic in llamas as reported earlier for other animals (2, 7).

Phage display is a powerful method for directing selection to a particular domain of the antigen. However, the phage display in *E. coli* may not be the best method of selecting for VHVs directed against LPS, since anti-LPS VHVs may interact with the endogenous LPS molecules, resulting in growth inhibition of the host and consequently in the loss of interesting anti-LPS VHVs. Alternative selection methods, such as yeast display, are currently under evaluation.

The selected VH5 5G was directed against an epitope deep in the LPS structure. Since it interacts with the LPS from an rfaC mutant strain of *N. meningitidis*, the epitope should be located in the lipid A or KDO residues. This part of the LPS is more conserved between gram-negative bacteria than the structures located more distally from lipid A. Accordingly, this VH1 proved to bind to LPS from different bacteria. The ELISA signal for mutants expressing shorter LPS molecules was higher than that for the wild-type strain. This is probably due to the better exposure of the VH1 epitope in these shorter LPS molecules.

LPS of *E. coli* strain TG1 cofractionated with the VHVs. It would be interesting to find out whether the LPS interacts with the VHVs during spheroplasting of *E. coli* or whether the interaction between VH1 and LPS occurs earlier in LPS biogenesis, that is, during the transport of the LPS through the periplasm. Even though this interaction did not result in any detectable phenotype, these VHVs may still form interesting research tools for the study of LPS biogenesis.

The selected VH5 5G was functional after a denaturation-renaturation cycle. This property of correct refolding, which is intrinsic to VHVs in general, may prove to be highly favorable for the applications of the anti-LPS VHVs in therapy, since a decontamination step might be required before its utilization in patients. The anti-LPS VH1 selected is a leading candidate in the development of therapies against LPS-mediated sepsis. The binding properties of the anti-LPS VH1 may be improved by in vitro evolution and protein engineering techniques to develop higher-affinity antibodies that will serve to capture LPS from the plasma of sepsis patients with greater efficiency than the current apheresis systems (1, 29). Nonselective apheresis, such as therapeutic plasma exchange, already shows a beneficial effect on the outcome of patients suffering from sepsis (27, 35). Redirection of the plasma through a column functionalized with anti-LPS VHVs may speed up the specific clearance of the LPS from the blood circulation and subsequently the recovery of the patient. Although most of the antipseudomonal therapies described in this paper are based on the utilization of only the VHH polypeptide, the utilization of the whole single-chain antibody, as well as the grafting of the selected antigen-binding domains on different immunoglobulins, is not discounted. Finally, anti-LPS VHVs can be produced at low cost on a large scale using microorganisms, resulting in an affordable therapy.

**ACKNOWLEDGMENTS**

We thank J. Geurtsen for *B. pertussis* LPS, for assistance with LPS isolation, and for mass spectrometry analysis of lipid A, M. Bos and L. Steeghs for exchange of materials and strains, and J. van Strijp for critical discussions.

This work was supported with financial aid from SenterNovem (TSGE 3131).
