Received 1 November 2005/Returned for modification 8 December 2005/Accepted 1 February 2006

In addition to cytokines, CD4+ T cells have been found to secrete soluble, T-cell-derived antigen binding molecules (TABMs). These antigen-specific immunoproteins are thought to have immunoregulatory properties in the suppression of cell-mediated immunity (CMI) because they often associate with interleukin-10 (IL-10) and transforming growth factor beta. Decreased CMI causes susceptibility to infections caused by organisms which are normally nonpathogenic. In this situation, e.g., Candida albicans saprophytism may develop into invasive candidiasis. The difficult diagnosis of invasive candidiasis is based on the findings obtained from blood cultures and with tissue biopsy specimens, with some additional diagnostic value gained by the detection of Candida albicans mannan antigenemia and antimannan antibodies. In the present study, Candida albicans mannan-specific TABM (CAM-TABM) levels in the sera of patients with invasive candidiasis (n = 11), Candida colonization (n = 11) and noncolonization (n = 10), recurrent vulvovaginal candidiasis (n = 30), and atopic eczema dermatitis syndrome (n = 59) and healthy controls (n = 30) were analyzed. For 14 participants, the effect of mannan stimulation on TABM production and gamma interferon (IFN-γ) and IL-4 mRNA expression by peripheral blood lymphocytes was also studied. It was demonstrated that CAM-TABM production was the highest in patients with invasive candidiasis and that CAM-TABM levels could distinguish Candida-colonized patients from noncolonized patients. In addition, the CAM-TABM level was directly related to mRNA expression for IL-4 but not IFN-γ. These results reinforce the view that TABMs are associated with decreased CMI, immunoregulation, and the T-helper cell 2-type immune response.

Based on their cytokine production, CD4+ T cells have been divided into Th1 and Th2 cells, with the former producing gamma interferon (IFN-γ), interleukin-2 (IL-2), and tumor necrosis factor beta and with the latter producing IL-4, IL-5, IL-10, and IL-13 (1, 57). The presentation of microbial antigens by dendritic cells (DCs) and macrophages to CD4+ T cells and the Th1-type cytokine production by these T cells are essential in cell-mediated immunity (CMI) (1). Decreased CMI gives rise to infections of normally nonpathogenic organisms, such as Candida albicans. A proper Th1-type response has proved crucial in the immune defense against C. albicans infections, whereas a Th2-type response predisposes the patient to invasive growth and recurrent or chronic infections (37). In a Th2-type immune response, T cells have been found to secrete, in addition to cytokines, soluble, T-cell receptor (TCR) α-chain-related, antigen-specific immunoproteins called T-cell-derived antigen binding molecules (TABMs), which recognize unprocessed antigens independently of major histocompatibility complex class I or II antigens (40, 50, 51). TABMs are thought to participate in the suppression of CMI by an immunoregulatory mechanism, e.g., by an antigen-specific focusing of IL-10 and transforming growth factor beta (TGF-β), because they often associate with these cytokines (4, 5, 26, 40). Furthermore, TABM- and TCR α-chain-related immunoprotein-induced delayed-type hypersensitivity suppression has been shown in anterior chamber-associated immune deviation of the eye, which is an in vivo example of the function of these proteins (11, 55).

Elevated, antigen-specific serum TABM levels have been detected in several diseases. These include C. albicans mannan-TABMs (CAM-TABMs) in recurrent vulvovaginal candidiasis (RVVC) and inflammatory bowel syndrome (24, 25); casein-, β-lactoglobulin- and α-lactalbumin-specific TABMs in milk intolerance (26); benzoic acid-TABMs in toluene sensitivity (18); and filarial extract-TABMs in chronic filariasis (24). All these TABMs were shown to carry the same epitope (3C9) detected by a monoclonal anti-TABM antibody, MG3C9-1A12 (24).

TABMs specific for Cetavlon-purified mannan polysaccharide of C. albicans (CAM-TABMs) were characterized by Little et al. (25). They proved cross-reactive because they also bound to C. albicans whole extract and other fungi, including Malassezia. In polyacrylamide gel electrophoresis, reduced, alkylated CAM-TABMs demonstrated 86-, 43-, and 22-kDa protein bands. Furthermore, CAM-TABMs did not contain immunoglobulins, whereas it was noticed that TABMs were associated with decreased CMI, immunoregulation, and the T-helper cell 2-type immune response.

*albicans*-specific TABM production is elevated in patients with invasive candidiasis and, thus, is associated with severely decreased CMI. Further aims were to evaluate *C. albicans* Cetavlon-mannan and whole extract antigen-specific TABMs for use in the differential diagnosis of *C. albicans*-induced invasive infection and *Candida* colonization and noncolonization and finally, to examine the effect of mannan stimulation on TABM production and IFN-γ and IL-4 mRNA expression by peripheral blood lymphocytes in vitro.

**MATERIALS AND METHODS**

**Study subjects.** Thirty-two patients who underwent abdominal surgery at the Department of Surgery of the University Central Hospital of Turku (Turku, Finland) participated in the study. Serum samples were taken when signs of septic or superficial infection were seen during the first postoperative week. The samples were stored at −70°C and analyzed retrospectively and had no influence on therapeutic decisions. The severity of fungal infection was determined retrospectively on the basis of clinical, microbiological, and autopsy records.

Thirty women from the Department of Gynaecology and Obstetrics of the University Central Hospital of Turku with RVVC were also included the study, and a serum sample was taken after the provision of informed consent. Fifty-nine patients with atopic eczema dermatitis syndrome (AEDS) from the Department of Dermatology of the University Central Hospital of Turku formed yet another reference patient group for the comparison of serum TABM levels. Furthermore, in a small group (*n* = 8) of yeast-hypersensitive AEDS patients, the level of TABM production was measured from the cell supernatants of *C. albicans* mannan-stimulated peripheral blood lymphocytes.

Finally, serum samples for TABM level determinations were collected from healthy volunteers (*n* = 30). Samples for peripheral blood lymphocyte stimulations were from laboratory personnel (*n* = 6).

Detailed data on the ages and genders of the study subjects and the inclusion and exclusion criteria used are presented in Table 1.

*a* The data represent medians (ranges).

*b* M, male; F, female.
The cell suspension was diluted in 200 whole-cell extract, used as an in-house reference (IHR) preparation, was pre-plates on synthetic medium as described earlier (45). The mannan antigen IgE (S-IgE) was analyzed by a Pharmacia IgE radioimmunoassay. Earlier (31).

were isolated with Ficoll-Hypaque (Amersham Pharmacia Biotech, Uppsala, Sweden) and applied to 96-well culture plates (Nunclon). A total of 100,000 cells/well were added, and the plates were incubated overnight at 4°C and washed. The supernatants of CAM-stimulated and nonstimulated peripheral blood lymphocytes were diluted 1:200 in PBS, 100 µ/l was added to each well in duplicate, and the plates were incubated overnight at 4°C and washed. The serum samples were diluted 1/200 in PBS, 100 µ/l was added, and the plates were incubated for 90 min at 37°C and washed. Peroxidase-conjugated rabbit anti-mouse immunoglobulin G (IgG; Dako F-0260; DakoCytomation, Glostrup, Denmark) was also diluted 1/1,000 in PTG, 100 µ/l was added, and the plates were incubated for 90 min at 37°C before they were washed with PBS-T. Mouse monoclonal anti-human TABM antibody was diluted 1/1,000 in PBS–Tween 1% gelatin (PTG; G-2625; Sigma-Aldrich), 100 µ/l was added, and the plates were incubated for 90 min at 37°C and washed.

Mannan ELISA. CAM, IHR, and M. furfur crude antigens. Antigen preparations were diluted in phosphate-buffered saline (PBS; CAM at 0.1 mg/ml, IHR and M. furfur at 1.0 mg/ml) and coated overnight at 4°C on separate flat-bottom microtiter plates (Nunc, Roskilde, Denmark). After the plates were washed with PBS-0.05% Tween 20 (PBS-T), they were blocked with 1% human serum albumin in PBS for 90 min at 37°C and washed. The serum samples were diluted 1:200 in PBS; 100 µ/l was added in duplicate, and the plates were incubated overnight at 4°C and washed with PBS-T. Mouse monoclonal anti-human TABM antibody was diluted 1/1,000 in PBS–Tween 1% gelatin (PTG; G-2625; Sigma-Aldrich), 100 µ/l was added, and the plates were incubated for 90 min at 37°C and washed. Peroxidase-conjugated rabbit anti-mouse immunoglobulin G (IgG; Dako F-0260; DakoCytomation, Glostrup, Denmark) was also diluted 1/1,000 in PTG, 100 µ/l was added, and the plates were incubated for 90 min at 37°C before they were washed with PBS-T. After the plates were washed with distilled water, 100 µ/l of tetramethylbenzidine hydrochloride substrate (Kirkegaard & Perry Laboratories, Inc., Gaithersburg, MD) was added and the reaction was allowed to proceed at room temperature until an optical density (OD) of approximately 1.5 was obtained. The reaction was stopped with 2 M H2SO4, and the plates were read at a wavelength of 450 nm with a Multiscan photometer (LabSystems, Helsinki, Finland). TABM OD values were converted to arbitrary enzyme-linked immunosorbent assay (ELISA) units (AU) (0 to 100 AUs) by using a linear graph produced with the aid of seven control serum samples with the maximum OD range.

Statistical analysis. Differences in serum TABM levels and the levels of cytokine mRNA expression between study groups were analyzed by the Mann-Whitney U test. The difference in the mean levels of TABM production between colonized and noncolonized patients was calculated by Student’s t test. Correlations were analyzed by regression analysis.

RESULTS

Statistically significant TABM differences between study groups. The C. albicans mannan-specific serum TABM levels of the different study groups are presented in Fig. 1A. TheCAM-TABM amount was the highest in the serum of patients with invasive candidiasis, and the difference was significant compared with the amounts in hospitalized patients and healthy controls but insignificant compared with the amounts in Candida-colonized patients. Candida-colonized patients had a tendency (P = 0.091) to have higher CAM-TABM levels than hospitalized patients. The lower level of CAM-TABMs in AEDS patients compared with that in RVVC patients did not quite reach statistical significance (P = 0.072). The differences between RVVC or AEDS patients and controls were insignificant.

Comparison of Fig. 1B with Fig. 1A shows that all the C. albicans IHR-specific TABM values were lower than the mannan-specific values. Still, the IHR-specific TABM levels in invasive candidiasis patients were significantly higher than those in both hospitalized and healthy subjects. No significant differences were seen between RVVC and AEDS patients and healthy controls.

TABM production in colonized versus noncolonized patients. After the exclusion of confirmed invasive candidiasis cases (n = 11) and healthy controls (n = 30), the rest of the patients with serum TABM samples (n = 110) were also examined for gastrointestinal C. albicans colonization based on positive or negative anal swab sample cultures. As further proof of CAM-TABM specificity in colonization and because 54% (59 of 110) of these patients had AEDS, we decided to determine the M. furfur-specific TABM levels as well. Colonized patients (n = 42) had significantly higher C. albicans mannan levels but not IHR- or M. furfur-specific TABM levels than noncolonized patients (n = 68) (Fig. 2).

Correlation between TABM production and serum immunoglobulins. Patients (n = 32) with invasive candidiasis, with Candida colonization, and in a postoperative state after abdominal surgery were tested for correlations between their CAM- and IHR-specific TABM and mannan-specific IgE, IgG, and IgM values. Significant correlations were found between both types of TABMs and mannan-specific IgM and IgG. Mannan-specific IgE and TABM levels did not correlate (Table 2). Serum samples of 46 yeast-hypersensitive AEDS patients
were available for correlation analysis between CAM-, IHR-,
or M. furfur-specific TABM levels and specific IgE and S-IgE
levels. There was not a significant correlation either between
antigen-specific TABM and IgE concentrations or between
TABM and S-IgE values (data not shown).

All serum samples (n/H11005 151) were also studied for antigen-
specific TABM level correlations. CAM- and IHR-specific
TABM levels had the highest correlation, followed by the cor-
relations between IHR- and M. furfur-specific and CAM- and
M. furfur-specific TABM levels (Fig. 3).

FIG. 1. C. albicans mannan-specific (A) and IHR-specific (B) TABM levels of the study groups. INV, invasive candidiasis patients (n = 11); COL, Candida-colonized patients (n = 11); HOSP, hospitalized, noncolonized patients who had undergone gastrointestinal surgery (n = 10); RVVC, recurrent vulvovaginal candidiasis patients (n = 30); AEDS-1, atopic eczema dermatitis syndrome patients, group 1 (n = 59), HC-1, healthy controls, group 1 (n = 30). Significant differences (P < 0.05, Mann-Whitney U test) are shown. The bars represent medians. TABM levels are expressed as arbitrary ELISA units (see Materials and Methods).

patients (n = 8) and healthy controls (n = 6) were also measured. It was noticed that mannan stimulation inhibited TABM production and IL-4 mRNA expression and increased IFN-γ mRNA expression in vitro (Fig. 4). When test subjects were divided into high-level (n = 7) and low-level (n = 7) TABM producers (TABM production indices greater than or equal to and less than −0.78, respectively), it was seen that IL-4 mRNA expression was significantly higher in high-level TABM-producing subjects than in low-level TABM-producing subjects (Fig. 5). Instead, there was no difference in IFN-γ mRNA expression between high- and low-level TABM producers (P = 0.57).

**DISCUSSION**

In this study it was demonstrated that *Candida albicans* mannan-specific TABM production was the highest in patients with invasive candidiasis and that CAM-TABM could distinguish *Candida*-colonized from noncolonized patients on a population basis. It was also shown that the CAM-specific and IHR-specific TABM levels correlated with each other and that the CAM-TABM levels correlated with mannan-specific IgM and IgG levels but not with IgE or S-IgE levels. In addition, it was demonstrated that CAM-TABM was directly related to IL-4 mRNA expression but not IFN-γ mRNA expression.

Decreased cell-mediated immunity and the dimorphism of *C. albicans*, i.e., the ability to change between the yeast and the hyphal forms, have been proved to be essential for the development of invasive candidiasis. It was shown in mice that a Th2-skewed immune response with elevated IL-4 and IL-10 production and decreased IL-12 production predisposed patients to invasive *Candida* infection (37–39). The virulence of *C. albicans* has been associated with the formation of hyphae, whereas the yeast form has proved avirulent (27). There is a decrease in the average chain length of mannoooligosaccharides, especially of β-1,2-linked mannose residues, in hyphal mannans compared with that in yeast mannans (47). β-1,2-Mannoooligosaccharide-induced humoral immune responses (IgM and IgG production) and cell-mediated immune responses (tumor necrosis factor alpha secretion by macrophages) might protect patients against invasive candidiasis (12, 16, 17). It is likely that DCs or macrophages discriminate between the yeast and the hyphal forms of *C. albicans* and influence the developing cytokine response by the ligation of Toll-like receptors (TLR). This is supported by the observation that TLR4 and TLR2 stimulation promoted Th1-type and Th2-type cytokine production in DCs, respectively (36). Furthermore, intact TLR4 was found to be essential for neutrophil recruitment to the site of *C. albicans* infection, whereas the recognition of *C. albicans* via TLR2 was noticed to induce immunosuppression mediated by increased IL-10 production and the survival of regulatory T (Treg) cells (32, 33). Montagnoli et al. were the first to demonstrate the induction of Treg cells during *C. albicans* infection (28). Based on these findings, it could be suggested that the *C. albicans* yeast form is recognized by DCs via TLR4, leading to a Th1-type immune response and candidal growth restriction, whereas decreased CMI allows hyphal transition, with TLR2-mediated DC activation leading to Treg cell up-regulation and invasive infection. This presumption was confirmed by van der Graaf et al. in a recent publication (52). It seems that invasive candidiasis and *C. albicans*-specific TABM production progress under similar immunological mechanisms, namely, depressed CMI, elevation of Treg cells, and increased Th2-type reactivity (5, 40, 50).

Mannan is a heterogeneous mixture of polymers of various sizes and charges (30). This enables the adequate binding affinity of mannan for plastic, and mannan has been used to coat ELISA plates since the 1980s (10). It was shown in this study...
that CAM-TABM values were the highest in invasive candidiasis patients, which might indicate a higher Th2-type immune response in their peripheral blood in comparison with that in patients with yeast-hypersensitive AEDS or RVVC. In fact, analysis of cytokines secreted by PBMCs or PBMC-derived T-cell clones of AEDS patients showed a predominance of IFN-γ production over IL-4 production (48, 53). In addition, we previously found that CAM-stimulated PBMCs of AEDS patients produced more IFN-γ and IL-2 than those of healthy controls (43), indicating elevated Th1-type immunity. Unlike in the earlier study by Little et al. (25), we noticed no difference between the CAM-TABM levels of RVVC patients and those of the controls in the present work, which probably resulted from the use of different patient material. The previous findings of cellular immunity in patients with RVVC have been controversial: after C. albicans stimulation, decreased (3, 6), similar (8), or increased (34) levels of lymphoproliferation and IFN-γ production of the PBMCs of RVVC patients compared with those of the PBMCs of controls were suggested.

Positive C. albicans anal swab specimen results indicating gastrointestinal colonization was noticed in 38% (42 of 110) of the study patients. The culture-positive, colonized patients had significantly elevated serum CAM-TABM values in this study. Since colonization usually precedes bloodstream or invasive Candida infection (35), it could be possible that patients with higher CAM-TABM levels are more at risk of invasive candidiasis if they display illnesses with decreased CMI or are being given broad-spectrum antibiotics. Therefore, even though CAM-TABM determination did not distinguish invasive candidiasis from Candida colonization, it might provide additional information when at-risk patients are evaluated. The TABM values of Candida-colonized patients and noncolonized control patients undergoing gastrointestinal surgery prove that TABM does not act as an acute-phase reactant. In the Candida-colonized group, there were no signs of septicemia or other invasive infections, although the TABM level was nearly as high as that in the group with invasive candidiasis. On the other hand, the TABM level in the group of noncolonized control patients who had undergone surgery was not elevated, even though they went through major abdominal surgery, which is known to cause the rapid and long-lasting release of acute-phase reactants, such as C-reactive protein, serum amyloid A, and IL-6 (2).

Mannan polysaccharide, a major yeast allergen, has proved cross-reactive at the level of specific IgE and the skin prick test (19, 41). It was therefore not surprising that the yeast antigen-specific TABM levels correlated as well. What surprised us was that the CAM-TABM level did not correlate with the mannan-specific or total IgE level, whereas it had a good correlation

![FIG. 4. CAM-TABM levels and the changes (Δ) in IL-4 and IFN-γ mRNA expression in cultures of PBMCs from AEDS patients (solid lines; n = 8) and healthy controls (dotted lines; n = 6) after 7 days of incubation with (CAM) and without (RPMI) mannan.](image)

with the IgG and IgM levels. It is known that the Th2-dependent extracellular antibody response initially requires T-cell help but expands in the absence of further T-cell involvement (49). We suggest that once a mannan IgE response is initiated, activated mast cells and basophils could substitute for Th2 cells in the B-cell interaction and further induce mannanspecific IgG production, because they express cell surface CD40L and secrete IL-4, both of which are needed for B-cell maturation (9).

The connection of TABMs to immunoregulatory cytokines (IL-10, TGF-β) and to the Th2-type immune response (5, 26) encouraged us to determine the levels of IL-4 and IFN-γ mRNA expression and TABM production of mannansimulated PBMCs. The significant, positive association between mannan-specific IgE production, because they express cell surface CD40L and secrete the B-cell interaction and further induce mannan-specific IgE activated mast cells and basophils could substitute for Th2 cells in (49). We suggest that once a mannan IgE response is initiated, help but expands in the absence of further T-cell involvement (9).
